**Abstract**  
**H. Stegmann, W. Kindermann, and A. Schnabel, Lactate Kinetics and Individual Anaerobic Threshold. Int. J. Sports Med. Vol. 2, No. 3, 160-165, 1981.**

Exercise with stepwise increasing work loads until exhaustion leads to a curvilinear increase of lactate in blood and typical lactate kinetics in the post-exercise period. Lactate kinetics in blood during exercise and recovery results from diffusion along gradients between muscle and blood and simultaneous elimination. Therefore, a general diffusion-elimination model is presented from which maximal rate of elimination ( $E_{\text{max}}$ ) is preassumed and from which individual anaerobic threshold (IAT), gradient between muscle and blood ( $\Delta C - \Delta E_m$ ), muscle volume working above the IAT ( $V_m$ ), individual membrane constant ( $M_c$ ), quantity of lactate accounting for lactate gradient ( $A_{\text{grad}}$ ), and whole body lactate ( $A_{\text{tot}}$ ) can be obtained. For demonstration purposes, this model was applied to a highly trained athlete. In this example, all constants and variables mentioned above as well as an equation reflecting individual lactate kinetics were calculated. Furthermore, the IAT was determined in 61 athletes participating in different events. In general, it can be demonstrated that with increasing aerobic capacity the lactate concentration at the IAT varies interindividual within broad limits, thus emphasizing the need for individual assessment.

**Key words:** lactate kinetics, physical exercise, diffusion, elimination, individual anaerobic threshold

tration curve. Therefore, the individual anaerobic threshold can be located above or below the 4 mmol/l blood lactate level. In this study, the lactate distribution in blood and muscle compartments during stepwise increasing work loads was determined by introducing a general diffusion-elimination model derived from blood lactate kinetics during exercise and the post-exercise period. By means of this model, the individual anaerobic threshold (IAT) was determined at individual lactate concentration levels and individual blood lactate inclination rates.

### Material and Methods

Considering diffusion through biological membranes (Eq. 1), the progressive increment of the blood lactate concentration during progressive work load (Fig. 1) reflects the increase of the lactate gradient  $\Delta C$  between working muscle and blood.

$$\text{Diffusion: } \left| \frac{dN(t)}{dt} \right| = M_c \cdot \Delta C \quad (1)$$

Simultaneously, the rate of lactate elimination  $E(t)$  must be considered (4, 15, 18). When the lactate concentration curve starts to rise, the increase in the diffusion rate exceeds the increase in the elimination rate. Near the steepest part of the curve in point A, the increment in the elimination rate can be considered negligible in relation to the increment in the diffusion rate. It can be concluded that the rate of elimination approaches a maximum (Eq. 1a).

$$\text{Elimination: } - \frac{dM(t)}{dt} = E(t) \quad (1a)$$
$$\rightarrow E_m = \text{const if } t \rightarrow t_A \quad (1a)$$

\*With the support of the Bundesinstitut für Sportwissenschaft, Köln-Bonn.

Lactate Kinetics and Individual Anaerobic Threshold

If a certain rate of diffusion is exceeded, an increase of the blood lactate concentrations in the initial post-exercise period ( $t > 1$  min) can be observed.

Equation 2 defines the point of time and work load where the maximal rate of elimination is in equilibrium with the rate of diffusion. This condition defines the IAT.

$$\text{if } t \leq t_{Em}$$

(二)

From Eq. 1 and 2, Eq. 3 is derived, describing lactate kinetics during exercise above the LAT:

$$\text{if } t > t_{Em} \quad \left| \frac{dn(1)}{dt} \right| = Em + Mc \cdot (\Delta C - \Delta CE_m)$$

$$\left. \frac{dE_m(t)}{dt} \right|_{\max} = E_m + MC \cdot (\Delta C_{\max} - \Delta C_{E_m}) \quad (3a)$$

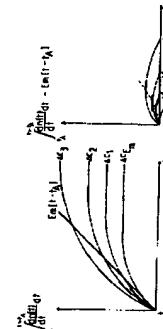

At point of time  $t_A$  (Fig. 1, cessation of work), the rate of diffusion and lactate gradient are maximal (Eq. 3a). In the post-exercise period ( $t > t_A$ ), the lactate gradient and consequently the rate of diffusion decrease (2). Figure 2a shows for different gradients (in  $t_A$ ) and their diffusion times the points of time where elimination  $E_m \cdot (t-t_A)$  meets diffusion  $\int_{t_A}^t \frac{dn(t)}{dt} dt$ . These are the intersection points of the straight line  $E_m \cdot (t-t_A)$  with the curves representing different amounts of diffusion  $\int_{t_A}^t \frac{dn(t)}{dt} dt$ . Diffusion and elimination acting simultaneously lead to points of intersection with different times.

in agreement with the  $\tau$ -axis as represented in Fig. 2b (gradient  $\Delta C_{Em}$  does not result in lactate increase in the post-exercise period). In the blood lactate concentration curve (Fig. 1), this condition is attained at time point  $t_B$  where the decreasing lactate concentration equals the concentration at point  $t_A$ . Time interval  $(t_B - t_A)$  is termed \*

[Integral within time limits to be omitted in

$$\int_{t_{\text{EM}}}^{t_{\text{EM}} + \Delta t} \frac{dV}{dt} dt = \int_{t_{\text{EM}}}^{t_{\text{EM}} + \Delta t} \frac{E_{\text{EM}} \cdot dI}{dI_{\text{EM}}} dt$$

Regarding Fig. 1, Eq. 7 results from Eq. 6 demonstrating that every  $(\text{Em}^*, \text{Lac}^*)$  is defined by the blood lactate concentration curve  $f(t_1)$  and the straight line resulting from  $(t_1 - t_{\text{Em}}^*)$  and that all points  $B'$  are located on the straight line  $\text{Em}^* = (\text{Em}^* - t_{\text{Em}}^*)$ , which is the tangent from a given B to the blood lactate curve.

**Fig. 2a** Time course of diffusion ( $\int_A \frac{g_{AB}(t)}{dt} dt$ ) according to different gradients ( $\Delta C_{EM}$  to  $\Delta C_A$ ) and elimination Em ( $t - t_A$ ) presented separately.

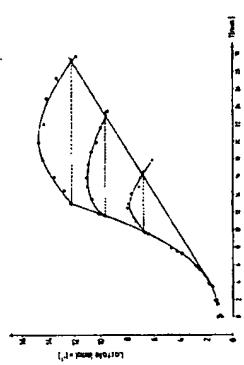

Fig. 3 Lactate kinetics in an untrained individual at different work loads. 0—0 exercise to exhaustion; 0—0 exercise up to 300 W; x—x exercise up to 250 W.

$$f(t_A) = Em \cdot (t_A - t_{Em}) + Em \cdot (t_B - t_A) = Em \cdot (t_B - t_{Em}) \quad (7)$$

$$Em \cdot (t_B - t_A) = f(t_A) - Em \cdot (t_A - t_{Em})$$

The contact point marks the individual anaerobic threshold (IAT), the ascent of the tangent the individual maximal elimination rate ( $Em$ ) according to Eq. 2. This can be confirmed experimentally. Figure 3 shows lactate kinetics for maximal and submaximal work loads on the bicycle ergometer in an untrained individual (different symbols mark different tests on consecutive days).

For each point of the blood lactate curve, the term  $Mc \cdot (1 + Vb/Vm)$  can be calculated by substituting for  $Em$ ,  $t_B$ , and  $dn(t)/dt$  into Eq. 5. Figure 4b depicts the changes of this term with time in three well-trained long-distance runners and the rower whose lactate curve is presented in Fig. 1 (time 0 marks IAT). Figure 4a shows changes of the factor  $(1 + Vb/Vm)$  with increasing muscle volume working above the IAT (expressed as multiple of the blood volume). The two curves are almost identical in shape. Accordingly, changes of  $Mc \cdot (1 + Vb/Vm)$  with time are considered to reflect changes of the muscle volume working above the IAT. Changes of  $Vm/Vb$  with time are determined by means of the standard curve in Fig. 4a, leading to the individual membrane constant ( $Mc$ ). For every point of a given blood lactate curve above the IAT, the corresponding lactate gradient can be calculated from:

$$\frac{dn(t)}{dt} - Em$$

$$Mc = \Delta C - \Delta C_{Em}$$

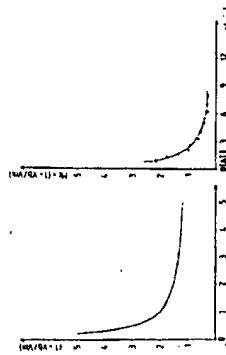

Fig. 4a Relationship of factor  $(1 + Vb/Vm)$  and increasing muscle volume  $(Vm/Vb)$ .  
Fig. 4b Time course of  $Mc \cdot (1 + Vb/Vm)$  as determined in o = a regional class long-distance runner; o = a German elite long-distance runner (up to 10,000 m); x = an international rowing champion in 3000 m; + = an international rowing champion (Fig. 1).

$$A_{grad} = Em \cdot t_{net} \cdot (Vm/Vb + 1) \cdot Vb$$

$Vb$  can be estimated by nomogram or from tables (Wiss. Tabellen, Dokumenta Geigy).

Determination of lactate distribution in body fluids is controversial (3, 13) as blood concentration levels must be considered to account for concentration levels in interstitial fluids as well. As elimination is defined as the decrease of lactate concentration with time in blood and muscle volume ( $Vm + Vb$ ), the total amount of body lactate at time point  $t_A$  (net lactate production:  $A_{net}$ ) can be calculated by  $Em$  multiplied by the time interval from  $t_A$  (cessation of work) to the point of time where the lactate concentration in the post-exercise period equals the lactate concentration in  $t_{Em}$  ( $t_{Em}$ ):

$$A_{net} = Em \cdot t_{net} \cdot (Vm/Vb + 1) \cdot Vb$$

$$A_{tot} = Em \cdot t_{Em} \cdot (Vm/Vb + 1) \cdot Vb$$

As elimination is considered to occur during exercise as well, total lactate production ( $A_{tot}$ ) can be obtained from calculation of  $Em$  over the time interval  $t_{Em} = (t_A - t_{Em})$ :

Sixty-two athletes from different events were subjected to different exercise tests (see data in Table 1); 38 males were tested on a motor-driven treadmill and 16 males and 8 females on an electrically braked bicycle ergometer.

### 1. Bicycle Ergometer

Swimmers (females): initial load 50 W, increment 50 W every 3 min

Swimmers and speed skaters (males): initial load 100 W, increment 50 W every 3 min

### 2. Treadmill

Physical education students and handball players: initial speed 6 km/h at a slope of 5%, increment 2 km/h every 3 min

Long-distance runners: initial speed 8 km/h at a slope of 5%, increment 2 km/h every 3 min

Subsequently it is easy to calculate the increment of the gradient per work load increment as well as the increase of muscle volume working above the IAT ( $Vm/Vb$ ). The amount of lactacid energy production can be calculated from the amount of lactate produced: a gradient multiplied by volume results in the quantity of lactate accounting for the lactate gradient:

Heart rate was determined from ECG recording during the last seconds of each work load. Oxygen uptake was measured continuously with an open system. Arterialized blood for enzymatic determination of lactate concentration (5) was taken with heparinized capillaries from the hyperemic earlobe at rest, at the end of each work load, and in the post-exercise period at 1, 2, 5, and 10 min from the termination of exercise.

**Results**

According to this diffusion-elimination model, individual assessment of the constants IAT, En, Mc and variables  $dn(t)/dt$ ,  $\Delta C - \Delta C_{\text{En}}$ , and  $Vm/Vb$  was done by a computer program in 61 athletes. The lactate concentration curve in Fig. 1 (international champion in rowing) may serve as an example ( $Vb = 7.0 \text{ l}$ ):

Data:

$$\begin{aligned} IAT &= 363 \text{ W} (3.0 \text{ mmol} \cdot \text{l}^{-1} \cdot \text{min}^{-1}) \\ En &= 0.516 \text{ mmol} \cdot \text{l}^{-1} \cdot \text{min}^{-1} \\ Mc &= 0.292 \text{ mmol} \cdot \text{l}^{-1} \end{aligned}$$

The gradient at the IAT (derived from Eq. 2):  
 $\Delta C_{\text{En}} = En/Mc = 1.76 \text{ mmol} \cdot \text{l}^{-1}$   
 Individual lactate kinetics follow Eq. 5:  
 $dn(t)/dt = 0.516 [1 + 0.292 \cdot \ln (1 + Vb/Vm)]$

The effect of exercise with stepwise increasing work loads above the IAT on individual lactate kinetics is shown in Table 2. The individual evaluation of lactate kinetics as demonstrated in Table 2 shows that the acceleration of the increment of the blood lactate curve ( $dn(t)/dt$ ) is paralleled in the increment of the gradient  $\Delta C$ . The increase of  $Vm/Vb$  indicates the increase of the muscle volume working above the IAT ( $Vm$ ). The maximal value in 62 athletes was 4.2. It never approached the physiologic limit of 5–6 (Wiss. Tab. Dok. Geigy, 1970).

Means of lactate concentration levels in blood during the exercise and post-exercise period were calculated for each group listed in Table 1. Figures 5 and 6 show the group means of the anaerobic threshold as determined from the

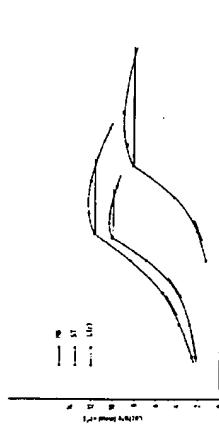

Fig. 5 Lactate kinetics in mean lactate concentration curves according to events (Table 1, treadmill exercise).

mean concentration curves. In addition, from each individual curve the anaerobic threshold was calculated. Table 3 shows means as well as upper and lower limits of lactate concentration and work load as determined individually.

#### Critical Evaluation of Experimental Settings

In conventional bicycle ergometer and treadmill tests (8), stepwise increasing work loads are used. Intermediate work loads are calculated by interpolation. To follow the relationship between work load and physiologic response more closely, exercise tests with continuously increasing work load may turn out to be preferable. Unlike in bicycle ergometer tests, blood sampling in treadmill tests requires interruption of work at the end of each interval, which leads to a decrease of the lactate gradient between blood and muscle. Whereas in treadmill tests blood is taken immediately after termination of work, in bicycle ergometer tests this can be done immediately before termination.

#### Discussion

The higher the work load in stepwise tests, the more the rate of elimination remains behind the rate of diffusion, leading to an increasing acceleration of the blood lactate curve.

By means of the model presented, the maximal rate of elimination ( $\dot{V}_{A\max}$ ) is determined at the blood lactate concentration curve by means of a tangent. The contact point defines the individual anaerobic threshold (AT).

The assumption that maximally induced rates of elimination ( $\dot{V}_{Em}$ ) do not change during inactivity in the post-exercise period seems to disagree with experimental evidence, indicating that work loads below the onset of blood lactate accumulation induce a faster decrease of the blood lactate concentration (1, 18, 4). During the first minutes of recovery, this effect appears to be negligible in magnitude. The experimental evidence presented in Fig. 3 supports this assumption, as rates of elimination seem to be similar for different  $t_{in}$  intervals. Whether this holds for very long  $t_{in}$  intervals, or time intervals less or ten cannot yet be decided. It may

turn out to be favorable to apply light work loads near the aerobic threshold (9) in the post-exercise periods, thus ensuring maximal rates of elimination.

It is an advantage of this model that for the assessment of total lactate turnover or the magnitude of the lactate space, the muscle volume working above the AT, and the maximal rate of elimination must not be substituted for by estimated values (3, 13). Evaluation of the amount of lactate accounting for a given gradient ( $\dot{V}_{grad}$ ) or net lactate production ( $\dot{V}_{net}$ ) takes into account individual lactate turnover, not only in one compartment (3, 12–14) but in Vm and Vb simultaneously.

The results indicate that individual determination of the anaerobic threshold or aerobic-anerobic threshold at fixed lactate concentrations (9, 11) or fixed increments of the lactate concentration (7) is not possible. Because of individual lactate kinetics, higher as well as lower lactate concentrations than 4 mmol/l (9, 11) were found within almost all study groups (Figs. 5 and 6, Table 3). The means of lactate concentration at the AT in groups of untrained subjects or athletes not especially endurance-trained was found near 4 mmol/l, whereas in endurance-trained subjects (especially in highly trained long-distance runners), it was found to be distinctively lower (Table 3). Thus, in cross-sectional studies, it has to be taken into account that determination of the AT at fixed lactate values may lead to wrong evaluation of endurance capacity. Individual lactate kinetics require individual determination of the anaerobic threshold (AT).

A paper dealing with 50-min tests at the IAT and at a fixed lactate concentration is in preparation. It will be published in one of the next issues of this journal.

Abbreviations	Dimension	Definition
$\dot{V}_{grad}$	mmol	Amount of lactate accounting for the lactate gradient
$\dot{V}_{net}$	mmol	Total amount of body lactate in $t_A$
$\dot{V}_{A\max}$	mmol	Total contribution of anaerobic energy metabolism to exercise in $t_A$

## Abbreviations continued:

Symbol	Dimension	Definition
$\Delta CE_{\text{in}}$	$\text{mmol} \cdot \text{l}^{-1}$	Lactate gradient at the IAT
$\Delta C_{\text{max}}$	$\text{mmol} \cdot \text{l}^{-1}$	Lactate gradient at $t_A$
$dC(t)/dt$	$\text{mmol} \cdot \text{l}^{-1} \cdot \text{min}^{-1}$	Rate of diffusion
$\dot{E}_{\text{in}}$	$\text{mmol} \cdot \text{l}^{-1} \cdot \text{min}^{-1}$	Maximal rate of elimination
IAT	-	Individual anaerobic threshold
$M_{\text{in}}$	$\text{min}^{-1}$	membrane constant: increase of the rate of diffusion if the gradient $\Delta C_{\text{max}} - \Delta C_{\text{in}}$ is increased by 1 $\text{mmol} \cdot \text{l}^{-1}$
$t_A$	min	Point of time of cessation of work in exercise with stepwise increasing work loads
$t_B$	min	Point of time when the lactate concentration in post-exercise period meets the lactate concentration in IAT
$t_{\text{Em}}$	min	Point of time during exercise with stepwise increasing work loads describing the IAT
$t_h$	min	Time interval ( $t_B - t_A$ ) needed for elimination of $A_{\text{grad}}$
$t_{\text{rest}}$	min	Time interval ( $t_X - t_A$ ) needed for elimination of $A_{\text{net}}$
$t_{\text{tot}}$	min	Time interval ( $t_X - t_{\text{Em}}$ ) needed for elimination of $A_{\text{tot}}$
$t_X$	min	Point of time when lactate concentration in post-exercise period meets lactate concentration in $t_{\text{Em}}$
$V_D$	l	Blood volume
$V_m$	l	Muscle volume working above IAT

### Onset of Blood Lactate Accumulation and Enzyme Activities in M. Vastus Lateralis in Man

B. Sjödin, I. Jacobs, and J. Karlsson  
 Laboratory for Human Performance, Dept. of Clinical Physiology, Karolinska Hospital and National Defense Research Institute, Stockholm, Sweden

#### Abstract

**B. Sjödin, I. Jacobs, and J. Karlsson, Onset of Blood Lactate Accumulation and Enzyme Activities in M. Vastus Lateralis in Man. Int J Sports Med. Vol 2, No 3, 166-170, 1981.**  
 In an earlier study, we reported close relationships between marathon running performance and the running velocity ( $V_{OBLA}$ ) at which the "onset of blood lactate accumulation" (VOBLA) occurs in a group of marathon runners. Using biopsy material from the m. vastus lateralis of the same subjects ( $n = 18$ ), we have evaluated the relationship of VOBLA to different muscle enzyme activities together with muscle fiber composition and capillary density in the present study. The activities of lactate dehydrogenase (LDH EC 1.1.1.27), phosphofructokinase (PFK EC 2.7.1.17), and citrate synthase (CS EC 4.1.3.7) were determined. VOBLA was negatively correlated to LDH ( $r = -0.54$ ) and PFK/CS ( $r = -0.68$ ). Using multiple regression analysis, the PFK/CS ratio together with the capillary density accounted for 81% of the variation in VOBLA. Absolute training kilometerage was the most significant parameter measured and accounted for 77% of the variation in VOBLA. Subjects were divided into elite runners ( $n = 6$ ) and nonelite runners ( $n = 13$ ) for an additional analysis of the relationship between VOBLA and the ratios of PFK/CS or LDH/CS. Significant relationships between VOBLA and the ratios were observed only in the nonelite runners ( $r = -0.77$  and  $-0.86$ , respectively). The vertical distances between the regression lines for these two subject groups could not be explained only on its basis of the enzyme activity ratios. A greater adaptation to fat combustion in the elite runners might explain the disproportionately high VOBLA in relation to the PFK/CS or LDH/CS activity ratios.

**Key words:** blood lactate, muscle fiber type, enzymes, endurance exercise

Tesch has demonstrated a positive relationship between the frequency of type II or fast twitch (FT) muscle fibers and lactate accumulation at onset of exercise under "nonsteady state" (transient) conditions (26). He also has observed a higher lactate release to the blood per unit of lactate formed in subjects rich in type I or slow twitch (ST) muscle fibers than in subjects rich in FT fibers (personal communication). A number of studies in man have demonstrated a higher oxidative potential in ST fibers than in FT fibers, which is augmented by endurance training (e.g., 8).

During muscular exercise, the extent of lactate formed from carbohydrate metabolism is a function of the balance between glycolytic stimulation and the capacity of the muscular respiratory system. Ivy et al. (9) reported a direct relationship between onset of plasma lactate accumulation (OPLA) and the rate of oxygen consumption in muscle homogenate when pyruvate was added as the substrate.

The present study was performed to further evaluate how the activity potential of the glycolytic and oxidative enzyme systems, plus muscle fiber composition, will influence blood lactate accumulation expressed as VOBLA.

#### Material and Methods

##### Subjects

Nineteen marathon runners participating in Stockholm's Marathon, 1979, gave their informed consent to participate in this study. Their age, height, and weight were (mean  $\pm$  SD)  $32 \pm 7$  yrs,  $179 \pm 6$  cm,  $78 \pm 7.9$  kg. The group was divided into two subgroups based on marathon running records and training background. Subgroup A ( $n = 6$ ) was characterized as "elite runners" with personal marathon beats between 2.18-2.40 h and had been training more than 100 km per week for at least 5 years. Their mean training volume per week 2 months before the race was  $135 \pm 34$  km  $\times$  week $^{-1}$ . Subgroup B ( $n = 13$ ) consisted of less experienced or "nonelite" runners with personal records above 3 h. They trained less than 100 km per week (mean  $\pm$  SD:  $53 \pm 21$  km  $\times$  week $^{-1}$ ) during the 2 months before the competition.

#### Functional Tests

The running velocity corresponding to onset of blood lactate accumulation ( $V_{OBLA}$ ) was determined during tread-

#### Introduction

The running velocity corresponding to onset of blood lactate accumulation ( $V_{OBLA}$ ) has been shown to be closely related to performance capacity in long-distance running (5, 23). It is also documented that the absolute as well as the relative exercise intensity at which blood lactate starts to accumulate is higher for endurance-trained subjects than for untrained subjects (3, 14, 18, 21). Muscle lactate accumulation (14) as well as lactate release (8) at given submaximal work loads are lower after endurance training and related to an increased muscle tissue respiratory capacity as indicated by succinate dehydrogenase activity.
